# BACKGROUND RADIATION FROM FISSION PULSES 

by<br>T. R. England, E. D. Arthur, M. C. Brady, and R. J. LaBauve

#### Abstract

Extensive source terms for beta, gamma, and neutrons following fission pulses are presented in various tabular and graphical forms. Neutron results from a wide range of fissioning nuclides (42) are examined and detailed information is provided for four fuels: ${ }^{235} \mathrm{U}$, ${ }^{238} \mathrm{U},{ }^{232} \mathrm{Th}$, and ${ }^{239} \mathrm{Pu}$; these bracket the range of the delayed spectra. Results at several cooling (decay) times are presented. For $\beta^{-}$and $\gamma$ spectra, only ${ }^{235} \mathrm{U}$ and ${ }^{239} \mathrm{Pu}$ results are given; fissionproduct data are currently inadequate for other fuels. The data base consists of all known measured data for individual fission products extensively supplemented with nuclear model results. The process is evolutionary, and therefore, the current base is summarized in sufficient detail for users to judge its quality. Comparisons with recent delayed neutron experiments and total $\beta$ - and $\gamma$ decay energies are included.

## I. INTRODUCTION

Two, and occasionally more, neutron rich nuclides remain following a neutron induced fission, as illustrated in Fig. 1. These fission products can be any one of approximately 1300 species, and they are all present in varying amounts following a sufficiently large number of fissions. Most nuclides are radioactive and coupled by their decay, as shown in Fig. 2 for 20 of the 1300 products. The initial amount of each product following a fission pulse is described by a probability per fission, or fission product yield, that varies with the fissioning species and with the initial neutron fission energy. Figure 3 is a simplified illustration of the distribution of the initially yielded products where Zp is the most probable product per mass chain. Figures 4 a and 4 b show the location of Zp and delayed neutron precursors for ${ }^{235} \mathrm{U}$ fast fission.

Fig. 1. Delayed neutrons from fission.

Fig. 2. Some explicit fission-product chains.

Fig. 3. Schematic of yield distribution.

Fig. 4a. Location of fission-product and delayed neutron precursors.

Fig. 4b. Location of fission product and delayed neutron precursors.

The total population of this plexus of products remains a constant in time equal to approximately twice the number of fissions in the pulse. However, the amount of each product changes continuously because of decay couplings, as do radiations associated with decay. Most of the decays are initiated by $\beta^{-}$transitions to excited states of the daughter product and are immediately followed by cascading gammas to lower energy states. In some cases ( $\sim 150$ ), the lower energy states are long-lived and can decay by either $\beta$ or an additional cascade of gammas to the ground state. In approximately 270 of the initial products, some of the $\beta$ - transitions leave the daughter product in an excited state exceeding the binding energy, $S(n)$, of a neutron and hence each such decay probably results in the emission of neutrons. In a very few cases $(<10)$, the parent nuclide of the neutron rich products decays by the emission of an alpha particle; however, the usual decays and radiations are illustrated in Fig. 5. Each of the $\beta^{-}$transition energies is actually a mixture of energies (in some continuous probability) of an electron and anti-neutrino and not a discrete value for either particle.

Fig. 5. Schematic of decay plus delayed neutron emission.

If we knew the fission-product yield, decay halflife, probability of each type of decay or branching fraction, and associated energy spectrum for each type of radiation, it would be possible to describe the time-dependent behavior and radiation field of the fission-product debris. We now have codes, notably, a version of CINDER ${ }^{1}$ and associated codes based on it, capable of calculating the time-dependence of each nuclide and each type of radiation for any mixture of fissioning nuclides. Basically, we first calculate the time-dependent quantity of each product and its activity and then fold in the various spectral types and sum these into an aggregate spectrum. The process is exact and the accuracy is limited by the uncertainties of the input data, some of this being based on measurements and some on nuclear models.

In this report, we describe the input source data of the nuclides available through fiscal year 1987 and present aggregate, time-dependent results of the total ensemble for the principal
radiations ( $\beta^{-}, \gamma$, and $n$ ). These form the dominant background radiations for any observer or instrument. The neutrons constitute a major portion of the discussion in this report.

The information in this report is intended as source data for further studies. For example, any detector will see additional temporal changes due to expanding debris, depending on its location. Here, all results describe isotropic radiation from a point source. The relative importance of the spatial expansion of the debris is dependent on each detector's location and is not considered here. The detectors are assumed to be shielded against the initial prompt neutron, x-ray, and gamma pulse sources. These can be calculated for any particular device, but they are not being included in this discussion. Here, the source terms apply to the continuously changing interference environment or background remaining following the fission pulse.

The background is device-dependent because of the mixture of fissioning nuclides and number of fissions. Except where noted, we have assumed that each pulse contains $1.3 \times 10^{26}$ fissions, or approximately the equivalent of $1 M T$, if all energy is from the fission of a single fissioning species.

The reader should be aware that measurements and improvements in nuclear models are currently in progress and results from these could significantly alter data for particular fission products. While changes in the aggregate total radiations are less likely to be significant, values at the large radiation energies could certainly change. The information in this report can be considered as the most extensive estimates of the radiation background to date and should serve as a reference or fiducial report for further studies.

## II. DATA BASE

Calculations require fission-product yields, nuclide halflives, decay branching fractions to isomeric and ground states of the daughter products and branching by those neutrons following beta decay (i.e., "delayed neutrons" or $\nabla_{d}$ ) and the beta, gamma, and neutron energy spectra for each nuclide. Except for spectra, all parameters are used to form chains of nuclides coupled, as in Fig. 2. (For fission pulses, we do not require neutron cross sections, but for extended irradiations, cross sections are required and these, like the delayed neutrons, cross couple the mass chains.)

## A. Yields

The fission-product yields in use are a preliminary, unpublished version for ENDF/B-VI, ${ }^{2}$ described in Ref. 3; mass chain yields are listed in Ref. 3 as well. All yield data are being updated and reevaluated prior to issue in Version VI of ENDF/B; the data in use are the most recent available and are current to about mid-1983. For this study, we did alter the ${ }^{238} \mathrm{U}$ fast-fission yields primarily in their distribution along the mass chains. The method of evaluation and the
distribution models are described in Ref. 3. (Only the ${ }^{238} \mathrm{U}$ proton pairing parameter was changed from values listed in that reference. The change was based on recent unpublished measurements made at Grenoble, France, and it resulted in a significant alteration in the calculation of delayed neutrons; however, it is less important to other aggregate quantities.)

Most high-energy neutron yields are based on nuclear models and systematics, not on measurements.

## B. Halflives and Decay Branching

Except for neutron branching (denoted as Pn ), these data are taken from ENDF/B-V ${ }^{2}$ and are listed in the summary document of Ref. 4. As noted in a later section, we now have sufficient tests to believe in their validity and the yield data can be assessed as generally very good.

## C. Beta/Gamma Spectra and Their Decay Energies

Earlier testing of these ENDF/B-V data ${ }^{2}$ demonstrated that measured nuclide spectra were usually deficient for many high-Q transitions.5,6 An earlier version of ENDF/B that relied more on nuclear model generated spectra showed better agreement with benchmark experiments than Version V. Other countries have also discovered the deficiency and the only reasonable recourse in the near future for individual nuclides is an augmentation of spectra using nuclear models. ${ }^{7}$ As discussed later, this has already been accomplished for total $\beta^{-}$and $\gamma$ decay energies, but not spectra, by the Japanese,,$^{8,9}$ with excellent results. As related to this report, the total $\beta^{-}$and $\gamma$ energies recommended by the Japanese are used in place of those in ENDF/B-V. Here, however, our primary interest is in aggregate spectra. For this purpose, we use 18- and 19-group functions fitted to our calculated spectra ${ }^{6}$ after some adjustment based on the measured spectra of Dickens ${ }^{10,11}$ reduced to a fission pulse. These functions also compare very well with measurements of total decay energies but apply only to ${ }^{235} \mathrm{U}$ and ${ }^{239} \mathrm{Pu}$ fission. We have no measured spectra for ${ }^{238} \mathrm{U}$ to use for similar fits. In any case, we need improved spectra for individual products if we are to use our developed capability for general spectra calculations for any fissioning nuclide.

## D. Pn Values and Delayed Neutron Spectra

These data were simply inadequate in any known evaluation/compilation. A very incomplete set of Pn values (delayed neutron branching fractions), but no individual spectra, exist in the ENDF/B files. Therefore, a large part of our effort to date on the nuclear background has been toward compiling, evaluating, and generating a complete set of delayed neutron data. The method of evaluating measured Pn's is described in Ref. 12. These data have now been revised through 1985 and appear in Section III. Measured Pn's now exist for 85 nuclides, but there are $>270$
nuclides having $\mathrm{Q}_{\beta}$ values exceeding the neutron binding energy $\mathrm{S}(\mathrm{n})$ based on nuclide masses. All are assumed to be delayed neutron precursors. This assumption is very reasonable; to date, all nuclides having the sufficient energetics (illustrated in Fig. 5) have been found to be neutron precursors.

Thirty-four of the precursors have one or more known spectral measurements. However, we have found no measured spectra prior to the beginning of this study that extend above 3 MeV , although many precursors have sufficient energetics for higher energy delayed neutrons. In these cases, it is necessary to augment the measurements with nuclear model calculations and to use models for the 237 unmeasured spectra, as was done in Ref. 13 for 76 spectra. Some model spectra can be important because of their large energy emission, but some are included simply for completeness, being relatively unimportant as a result of small Pn and/or yield values.

All measured spectra are normalized; also, prior to normalization, experimental data were generally missing at both low and high energy values. With the exception of 4 , all of the 34 measured spectra had to be augmented with model values. Thus, 241 of the 271 precursor spectra include some model values and 237 are based totally on models.

Table I summarizes the experimental spectra source and Table II, the general content of the data base. This extensive base is a dominant part of this report and will be further described in Section III. Reference 14 also provides a summary of the effort through September 1986; also a dissertation in preparation by a co-author of this report, ${ }^{15}$ will provide detail relevant to each change made to date in measured spectra. (The dissertation is primarily concerned with aggregate steady-state spectra $<3 \mathrm{MeV}$ important to reactors. Spectra at larger energies for some individual precursors will be discussed in the dissertation only because of the need to extend spectra to obtain a proper normalization. For this purpose, it will contain some information from Refs. 14 and 16).

The extensive Los Alamos data base for delayed neutrons is summarized in more detail in the following section. It results from national and international cooperation with periodic research over the past ten years and from an intensive effort over the past three years.

A general bibliography for delayed neutrons is attached as Appendix A of this report.

TABLE I

## SUMMARY OF EXPERIMENTAL SPECTRA

Studsvik measurements:
${ }^{3} \mathrm{He}$ spectrometers
On-line isotope separator Measurements for $\sim 25$ precursor nuclides Energy range $\sim 100 \mathrm{keV}-2 \mathrm{MeV}$

Mainz measurements:
${ }^{3} \mathrm{He}$ spectrometers
On-line isotope separator Measurements for $\sim 23$ precursor nuclides Energy range $\sim 40 \mathrm{keV}-3 \mathrm{MeV}$

INEL measurements:
Proton-recoil spectrometer
On-line isotope separator (TRISTAN-ISOL)
Measurements for 8 precursor nuclides
Energy range $\sim 10 \mathrm{keV}-1300 \mathrm{keV}$

TABLE II

## III. DELAYED NEUTRONS: CURRENT DATA EVALUATION

As noted in Section II(D), of the 271 probable delayed precursors, only 34 have measured spectra and 85 have measured emission probabilities ( Pn values). Such number comparisons can be misleading. As stated in Ref. 13, we found that 29 precursors having spectral measurements account for $70-82 \%$ of the total delayed neutron emission rate at equilibrium. For fission pulses, the 34 measured precursors account for $75-99 \%$ of the total rate at various cooling times. (The percentage increases monotonically with cooling time.) Furthermore, most measured spectra do not cover the complete energy range and some unmeasured short-lived precursors are likely to produce a large fraction of the neutrons at high energies. In addition, complete Pn data are needed in fission-product yield evaluations.

## Precursor Data

Table III lists Pn values for 271 nuclides and provides details on the bases of data for these and each spectra in the current data files. The table is important because it is a succinct record of the augmentations made in measured spectral data and in the origin of major data sources used in the systematic and nuclear models. For example, under the column labelled "Spectra Source," the notation for ${ }^{95} \mathrm{Rb}$ is (m) GO. 2 M 1.8 B . The " $(\mathrm{m})$ " denotes that the spectra are based primarily on measurements; but, for reasons to be described, the spectral shape below 0.2 MeV comes from INEL measurements by Greenwood and Caffrey, ${ }^{17}$ and, above 1.8 MeV [up to $\mathrm{Q} \beta-\mathrm{S}(\mathrm{n})=4.952$ $\mathrm{MeV}]$, the shape is based on the BETA code model. ${ }^{18}$ The dominant part of the emitted neutrons come, in this case, from measurements at the University of Mainz and are supplied by K. -L. Kratz, ${ }^{19}$ and other cases use data supplied by G. Rudstam. ${ }^{20}$ The $4.952-\mathrm{MeV}$ energy window is based on mass tables referenced under columns M1, M2, and M3, where MN refers to MöllerNix, ${ }^{21}$ and W81 refers to a preliminary unpublished version of the W83 Wapstra and Audi 1983 mass table (published in 1985). ${ }^{22} \mathrm{Q} \beta$ depends on the parent and daughter masses [sources under M1 and M2, and $\mathrm{S}(\mathrm{n})$ on the daughter and granddaughter masses (sources under M2 and M3)]. Values listed under "Norm Area" define the range used to renormalize the low- and high-energy spectra to the experimental data.

Only the notations under "Spectra Source" require such a detailed explanation. In general, the G, M, and R, respectively, refer to the INEL, Mainz, and Studsvik measurements, B to the BETA code, and EVAP to an evaporation model to be described. Only 4 of the 34 measured spectra have no modification. [These have "MAINZ" or "RUDSTAM" indicated following the " $\left.(\mathrm{m})^{\prime \prime}\right]$. The reasons for modification are discussed later in this section.

(Cont1 nued)
aGeneral Notes
This table contains the latest evaluated Pn values (10/86). Values indicated as derived from systematics are based on a least squares fit of the evaluated Pn values to the parameters in the Herrmann-Kratz equation. (The current spectral file is labeled tp3final.)

CS - chemical symbol
ID - nuclide $\mathrm{D}=10000 * \mathrm{Z}+10 * \mathrm{~A}+\mathrm{S}$
HL - halflife in seconds (For most nuclides, these values are taken from the ENDF/B-V summary, Ref. 4.)
Pn - probability of delayed neutron emission in per cent
dPn - uncertainty in Pn value ( 0.0 for calculated values)
GP - indicates which of the six temporal groups the nuclide probably belongs in.
$\mathrm{Q}_{\beta}$ and $\mathrm{S}(\mathrm{n})$ are in MeV .
Norm Area 1 and Norm Area 2 give the energy bounds in MeV being used in normalizing the spectra that were joined at the energies indicated under spectra source where energies are also in MeV and

B - BETA Code
G - Greenwood and Caffrey experimental data
M- Mainz group experimental data (K. Kratz and progress reports)
R - Rudstam (Studsvik) experimental data
E - Evaporation model
M1 - source of mass of $Z, A$
M2 - source of mass of $Z+1, A$
M3 - source of mass of $Z+1, A-1$
MN - Möller-Nix (Ref. 21)
W81 - Wapstra81 (Intermediate version of Ref. 22)
W83 - Wapstra83 (Ref, 22)
If the spectrum source is "EVAP," the temperature parameter in keV is given in parentheses.
** A fictitious $\mathrm{S}(\mathrm{n})$ is given this nuclide to obtain a positive energy window. Möller-Nix masses give a negative energy window. However, this precursor has a measured Pn value.
\# Most evaporation spectra were calculated using W81 or MN masses; some nuclides do have Wapstra83 masses available. W83 masses agree with those used to calculate this evaporation spectra (in terms of energy difference) with the exception of those indicated by \#. [For \#Cs-148, the W81 values give an energy window $=0.411 \mathrm{MeV}$ larger than the W 83 masses $\left(\mathrm{Q}_{\beta}\right)=10.92$, $S(n)=5.6, \mathrm{Pn}=6.9075)$.]

The systematic Pn values are from the Kratz-Hermann equation using Fred Mann's fit for $a$ and $b$ from the Birmingham meeting, September $1986[a=54.0, b=3.44$. $]$

Pn values and uncertainties are listed in per cent. Eighty-five are based on an updated evaluation (through 1986), including recent, unpublished data by Reeder and Warner. ${ }^{23}$ The evaluation uses the methodology we described in Ref. 12; the updating is described in Ref. 24 (to be published). The 85 Pn values have the notation "meas." under the column Pn Source. The rest use the $\mathrm{Q}_{\beta}$ and $\mathrm{S}(\mathrm{n})$ values in the systematic equation of Hermann and Kratz: 25

$$
\begin{equation*}
\left.\mathrm{Pn}=\mathrm{a}\left[\mathrm{Q}_{\beta}-\mathrm{S}(\mathrm{n})\right) /\left(\mathrm{Q}_{\beta}-K\right)\right]^{\mathrm{b}}, \tag{1}
\end{equation*}
$$

where $\mathrm{b}(=3.44)$ and $\mathrm{a}(=54.0)$ are fitted to the evaluated Pn's and

$$
\begin{aligned}
\mathrm{K} & =0 & & \text { even-even precursor } \\
& =13 / \mathrm{A}^{1 / 2} & & \text { odd precursor } \\
& =26 / \mathrm{A}^{1 / 2} & & \text { odd-odd precursor. }
\end{aligned}
$$

Exceptions to these general statements are either evident or explicity noted in the table.
Some of the problems found with measured spectra and with model approximations are illustrated in Figs. 6-12. The data for the nuclides ${ }^{94 g R b}$ (Figs. 6 and 7), ${ }^{96 g R b}$ (Figs. 8 and 9), and 92 gRb (Figs. 10 and 11) are plotted in two forms: the three different nuclide spectra are conventional histogram plots, followed by the same information plotted after its conversion to the fractional number of neutrons above the abscissa energy. The fractional plots emphasize differences at high energies, and are therefore more useful in comparison with some measurements now in progress. The range of the abscissa for these six plots is identical to the energy window, $\mathrm{Q}_{\beta}-\mathrm{S}(\mathrm{n})$, derived from mass tables. The general shape of the experimental spectrum in Fig. 6 is typical; clearly, in measurements over the total energy range, the higher range of possible neutron energies would be very uncertain due to the relatively low counting rate. Model calculations extend over the full energy range, and in this case, follow the general shape of the measured spectra; these models cannot, however, reproduce the actual fine structure.

Fig. 12. Normalized delayed neutron spectra for 95 gRb .

In Fig. 8 a primary problem occurring with existing measured spectra and our models is more evident. Measured spectra extend to only $\sim 2.5 \mathrm{MeV}$ and are normalized over this range; yet the energy window is $\sim 5.9 \mathrm{MeV}$. Here, the model spectra are clearly incorrect at low energies and the measured spectral range is probably inadequate. This is the case with at least 20 of the 34 measured spectra. Essentially all single measurements are likely to be incomplete in the sense of covering the total energy range. Thus, some are also inadequate at low energies ( $\leq 100 \mathrm{keV}$ ), important in reactors. Attempts here to combine spectra suffer from the problem of normalizations, although this is less severe than suggested by Figs. 8 and 9. As noted earlier, measured spectra do include most of the neutrons but their energy range is usually inadequate.

Figures 10 and 11 illustrate a different, less common problem. The measured spectrum decidedly has a background that must be removed. This appears to be evident from the figures and must be so if the $0.754-\mathrm{MeV}$ energy window is correct.

Figure 12 compares three measured spectra. In this case, normalization affects the comparison of even the measured spectra, especially because of the very large differences in the
low-energy peak, although there are real differences that are more evident when comparing ratios of various peaks; ratios are unaffected by normalization.

Our first objective in the current work has been to obtain a complete, fiducial set of precursor data, including data for all probable precursors and a complete energy range for the spectra. This has required some decisions that are in part subjective in the choice of spectral models, measured data to be combined, and the specific method of combination. Table III defines precisely what was combined or used for each precursor. In the case of more than one measurement being available, of the 34 precursors having measurements, we generally used the one covering the largest energy range. There are exceptions based on a comparison of uncertainties. The measurement was assumed to contain essentially all of the neutrons, and any model spectra were first renormalized to this dominant measurement, based on a small energy range defined in Table III. Results were then joined and the total spectrum was renormalized. The available hydrogen recoil measurements ( 8 precursors) made at Idaho National Engineering Laboratory (INEL) ${ }^{17}$ were assumed to be more correct at small energies than the data using ${ }^{3} \mathrm{He}$ spectrometry. ${ }^{19,20}$ These were similarly joined below 200 keV , as were the model results (below approximately 100 keV ) in 12 cases.

The combined spectra from models generally had little effect on the initial experimental data, as is evident in Fig. 13 where the dashed and solid plots are essentially the same. The range of results from various other combinations is illustrated by Figs. 13-16.

The BETA code ${ }^{18}$ was combined only with the 34 measured spectra where it could be normalized to a small range of measured data. This code is described in Ref. 18, as well as in Ref. 13, where it was used extensively. From the previous comparisons, the code clearly needs improvement before using it where no measured data exist to replace its low-energy predictions. Rather, most spectra have a general shape that can be approximated by a simple evaporation model.

The following evaporation model was employed for the 231 precursors having unmeasured spectra:

$$
\begin{equation*}
\mathrm{n}_{\mathrm{d}}(\mathrm{E})=\mathrm{C}\left\{\mathrm{E} \mathrm{e}^{-\mathrm{E} / \mathrm{T}}-\left(\mathrm{Q}_{\beta}-\mathrm{S}(\mathrm{n})\right) \mathrm{e}^{-\mathrm{aT}}\right\}, \tag{2}
\end{equation*}
$$

where

$$
\begin{equation*}
\left(\mathrm{Q}_{\beta}-\mathrm{S}(\mathrm{n})\right)=\mathrm{aT}^{2} . \tag{3}
\end{equation*}
$$

From Eq. (2), the average energy is $\bar{E} \cong 2 T$. We used the known spectra to derive an average energy and to then find a value of "a" in Eq. (3), based on the $\mathrm{Q}_{\beta}$ and $\mathrm{S}(\mathrm{n})$ values. The results were used to find a general correlation between " a " and the nuclide mass number:

$$
\begin{equation*}
a \cong 2 / 3 \mathrm{~A} \tag{4}
\end{equation*}
$$

Based on this and on Eq. (3), the temperature we derived is listed in Table III for each precursor in which the spectra are noted as being "EVAP," i.e., derived from Eq. (2).

Fig. 13. Normalized delayed neutron spectra for ${ }^{94} \mathrm{Rb}$.

Fig. 15. Normalized delayed neutron spectra for ${ }^{143} \mathrm{Cs}$.

Fig. 16. Normalized delayed neutron spectra for ${ }^{134} \mathrm{Sn}$.

In an attempt to verify the general validity of the extended spectra, a measurement was made of ${ }^{96} \mathrm{Rb}$ and ${ }^{97} \mathrm{Rb}$. Results from Ref. 16 show a preliminary comparison with our spectra converted to counts/channel in Figs. 17-18. More recently, we compared the ${ }^{96} \mathrm{Rb}$ as an energy plot with the measured spectra extended by both the BETA code and evaporation models, as shown in Fig. 19. The measured spectra fall between the two extensions. (Here, the measured spectra were normalized to earlier and more detailed measurements of Kratz ${ }^{19}$ over their common energy range.) From Figs. 17-19, the higher energy neutrons are obviously present, but there is a large uncertainty in any particular spectrum. The aggregate spectra could be significantly larger or smaller than values shown in Section IV.

Fig. 18. ${ }^{97} \mathrm{Rb}$ delayed neutron spectrum.

Fig. 19. Comparison of delayed neutron spectra for ${ }^{96} \mathrm{Rb}$.

Prior to 1986 there were no aggregate measurements $\geq 1.6 \mathrm{MeV}$. Very preliminary measurements were made at Los Alamos for ${ }^{235} \mathrm{U}$ samples irradiated by bursts from the Godiva reactor. Results reported in Ref. 16 are shown in Figs. 20-22, where the histograms are the measured spectra and the solid lines are our calculated results in 1986. Again, results are very uncertain at high energies but demonstrate the existence of the high-energy delayed neutrons.

## IV. CALCULATED $\nabla_{d}$ SPECTRA FROM FISSION PULSES

All of the data discussed in Section III were used in the CINDER-10 code to calculate the 271 precursor activities vs time following a fission pulse. The code includes all known fission products coupled together by all known decay branching. There is no approximation in the calculation other than the accuracy of the input data.

Normalized spectra and Pn values are folded into the precursor activities at various times to produce aggregate spectra and integrated delayed neutron rates for several fissioning species.

The fission pulse consists of $1.3 \times 10^{26}$ fissions over $10^{-4} \mathrm{~s}$. Table IV is an exception. Here, total $\nabla_{d}$ values at time zero are based on 100 fissions for each of 42 fissioning species. This table was actually produced using the Pn values, direct fission yields, and precursor halflives. Such calculations are relatively simple, but cannot describe the subsequent temporal variations in totals or in aggregate spectra. Table IV does show the importance of various fissioning systems except for hardness of the spectrum; and we have used these results to verify the CINDER-10 calculations at time $\sim 0$ (calculated results labelled as time $=0$ are actually values that apply at $10^{-4}$ s).

The temporal variation of each of these 42 cases has been calculated. In this report we primarily include the results for four fuels: ${ }^{235} \mathrm{U},{ }^{238} \mathrm{U},{ }^{239} \mathrm{Pu}$, and ${ }^{232} \mathrm{Th}$-all at fast or fission neutron energies. These bracket the range of calculated spectra. Figure 23 does show the total $\nabla_{d}$ rate vs time for eight of the fuels.

Figure 24 shows a comparison of the ${ }^{235} \mathrm{U}$ spectra at 5 s cooling before and after spectral expansions. Also included is an independent calculation made by A. Sierk ${ }^{14}$ using a totally statistical approach to both spectra and fission yields as a check on the general validity of results in this report.

Figures 25-28 show the spectrum for each of four fuels as a fraction of the delayed neutron rate remaining above the abscissa energy. Values at nine decay times are plotted. Total values'and average energies are included on the plots. Figures 29-31 compare these fractions for each fuel at 1,5 , and 10 s and Figs. 32 and 33 show the same data in more detail above 4 MeV .

The inclusion of ${ }^{232} \mathrm{Th}$ is based on its total $\nabla_{\mathrm{d}}$ rate. When the total spectrum is compared with ${ }^{238} \mathrm{U},{ }^{232} \mathrm{Th}$ is the larger value at most times. This is shown at three times in the comparisons of Figs. $34-36 .{ }^{239} \mathrm{Pu}$ is smaller at all times and energies. The range of spectra above 4 MeV found for the eight fuels plotted in Fig. 23 is shown in Fig. 37 at 5 -s decay.

Fig. 37. Absolute delayed neutron spectra per fission for $\mathrm{E}>4 \mathrm{MeV}$.
There is a dependence of the spectra on the incident energy. Figure 38 shows this for ${ }^{235} \mathrm{U}$ at 1 and 14 MeV at 5 -s decay, the value at 1 MeV being significantly larger at all energies. This is generally true for all fuels.

Appendix B tabulates precursors with contributions greater than $0.01 \%$ at various times above 0 and 4 MeV . The more important high-energy emitters are also identified in Fig. 4; specifically isotopes of $\mathrm{As}, \mathrm{Br}, I$, and $R b$ are important at energies above 4 MeV for decay times between 1 and 10 s . Measurements of a few of these at energies $>3 \mathrm{MeV}$ could greatly improve calculations for the various fuels and provide tests for the nuclear models that must be used for most of the precursors.

The reader is reminded that measured data exist for a small fraction of the number of probable precursors and their energy range, as illustrated in Fig. 39.

Fig. 39. Number of precursors having energies $>\mathrm{E}$.

Finally, some readers will be interested in the conventional six-time group approximations to these results. This has been made for most fuels and will be of most interest to reactor designers. Results for some fuels have been published in Refs. 26 and 27 and will be discussed in detail in the aforementioned dissertation (Ref. 15).

## V. DELAYED $\beta \cdot$ AND $\gamma$ RADIATION FROM FISSION PRODUCTS

Delayed radiations are considered to be occurring later than $10^{-4} \mathrm{~s}$ after the fission pulse. The fields coming from approximately 800 different radioactive products coupled by decay produce $\beta^{-}$ and $\gamma$ rays as well as delayed neutrons. The ensemble varies with fissioning species, fission neutron energy, and with time.

To evaluate the nuclear background following a nuclear explosion, we explicitly include all nuclides in several hundred chains that typically consist of 6 to 20 nuclides each (isotopes and isomers). For this, we need to know the initial yield of each nuclide, nuclide halflives, branching fractions per decay, and the detailed $\beta^{-}$and $\gamma$ energy distributions, as discussed in Secs. I and II, and in Ref. 4.

While the method of calculating the aggregate radiation fields from this plexus is exact, the data are not. Measured and evaluated data per nuclide are used if known; otherwise we necessarily resort to systematics and nuclear models. There are measured spectra for 300 of the approximately 800 radioactive products, and spectra based on systematics were constructed for the remaining, less important, unmeasured products. For three fissioning nuclides, namely, ${ }^{235} \mathrm{U},{ }^{239} \mathrm{Pu}$, and ${ }^{241} \mathrm{Pu}$ at thermal neutron fission energies, there are high quality aggregate spectra measurements to 7.5 MeV to use in validations. Investigations based on these experiments have revealed that at least 50 of the most important individual products are missing high energy gamma transitions. The resulting aggregate calculations show a gamma energy that is too small and a spectrum that is skewed towards low energy emission. (The opposite is true for beta spectra.) The number of important products having a deficiency is too large to be corrected with a few selected measurements, so the data base must be augmented with nuclear model calculations.

We have improved aggregate spectra for ${ }^{235} \mathrm{U}$ and ${ }^{239} \mathrm{Pu}$ using the recent ORNL measurements of Refs. 10 and 11. With the exception of ${ }^{241} \mathrm{Pu}$, this cannot be done for other fuels.

By plotting the spectra as a fraction of the energy remaining above the abscissa energy, as in Sec. IV for $\nabla_{d}$, we can compare the temporal variations of $\beta-\gamma$, and delayed neutrons. This is done in Figs. 40-43 at four cooling times. Here one can see the relatively rapid drop in highenergy neutrons vs time compared with $\beta^{-}$and $\gamma$ energies. As noted on these plots, the average and total $\beta^{-}$and $\gamma$ energies are larger at all times than values for delayed neutrons.

New decay heat measurements are currently being made in Japan 8,9 and we are in the process of including these data in our files as they become available. Figures $44-47$ show comparisons of Japanese measurements of $\beta$ - and $\gamma$ decay heat for ${ }^{238} \mathrm{U}$ and ${ }^{232} \mathrm{Th}$ with our calculations using data from ENDF/B-IV and ENDF/B-V. These figures clearly illustrate the need for updating our files. We anticipate that the Japanese will soon make available new spectral measurements that would be useful in additional file improvements. Thus, considering the promise of new measurements,
along with development and application of nuclear model codes, we expect to be able to greatly improve our data base, and, consequently, improve our predictive capabilities during the next year.

## VI. SUMMARY

The dominant radiation fields produced by nuclear devices are neutron, electromagnetic ( $x$ ray and gamma), and electron, each being prompt and delayed, and all being device dependent. In this report we have focussed on the delayed radiation fields that come from about 800 different radioactive products, 270 of which are delayed neutron emitters and all of which produce spectra of $\beta$ - and $\gamma$ energies. The initial content of this ensemble is characterized by a fission-product yield that varies with the type of device.

To predict this radiation background, we require a complete data base for each product and various application codes. These now exist, but the data bases require improvement because of the emphasis on high radiation energies, the need to examine different fissioning species and devices, and the need to predict fission-product yields from a fission pulse. Some improvements can be made with selected measurements, but many will require nuclear model calculations because of the large number of difficult measurements needed. With sufficient support, progress can be made in updating the necessary data bases during the next year by incorporating US, Japanese, and other measurements, and by developing and applying the necessary model codes.

## ACKNOWLEDGMENTS

Drs. F. M. Mann (Hanford Engineering Development Laboratory), P. L. Reeder (Pacific Northwest Laboratory), C. Goulding (Los Alamos National Laboratory), T. Yoshida (Nippon Atomic Industry Group), K. -L. Kratz (University of Mainz), and G. Rudstam (Swedish Research Councils Laboratory, Studsvik) contributed portions of data used in this report, as did others noted in the references. Several people, in addition to C. Goulding, were involved in the Los Alamos measurements (see Ref. 16). Most of the recent calculations were encouraged and supported by a Los Alamos program directed by G. F. Auchampaugh and earlier calculations were promoted by O. P. Judd. The basic data development was supported primarily by the US Department of Energy (Basic Energy Sciences).

## APPENDIX B INDIVIDUAL PRECURSOR CONTRIBUTIONS

In Section I we identified the major contributors at high energies (Figs. 4a and 4b, where arsenic, bromine, rubidium, and iodine isotopes are explicitly noted). In this appendix more detail is provided; specifically, for ${ }^{235} \mathrm{U},{ }^{238} \mathrm{U},{ }^{232} \mathrm{Th}$, and ${ }^{239} \mathrm{Pu}$ fast fission, the per cent contribution of each precursor to the total overall energy and to the total value above 4 MeV is listed for $\sim 0$, $1.0,5.0,10.0$, and 30.0 s . Only contributions $>0.01 \%$ are included. (Table B-I lists precursors having energies greater than $2,3,4,5,6,7$, and 8 MeV , but not their actual contribution to delayed neutrons.) Aggregate totals were included in Section IV.

Tables B-II through B-IX are intended to serve as a guide in the determination of the probable importance to calculations of future precursor experiments. It is important for the user to realize that the listed contributions above 4 MeV are based entirely on fission-product yields, emission probabilities, and delayed neutron spectrum models. Any single value could easily be in error by an order of magnitude; and, if so, all other relative contributions would change. Thus, a listed small contribution above 4 MeV should not discourage a possible measurement.

TABLE B-I
PRECURSORS HAVING PROBABLE DELAYED NEUTRON ENERGIES

## ABOVE NOTED VALUES
